Madani R, Karastergiou K, Ogston NC, Miheisi N, Bhome R, Haloo N, Tan GD, Karpe F, Malone-Lee J, Hashemi M, Jahangiri M, Mohamed-Ali V. RANTES release by human adipose tissue in vivo and evidence for depot-specific differences. Am J Physiol Endocrinol Metab 296: E1262–E1268, 2009. First published February 24, 2009; doi:10.1152/ajpendo.90511.2008.—Obesity is associated with elevated inflammatory signals from various adipose tissue depots. This study aimed to evaluate release of regulated on activation, normal T cell expressed and secreted (RANTES) by human adipose tissue in vivo and ex vivo, in reference to monocyte chemoattractant protein-1 (MCP-1) and interleukin-6 (IL-6) release. Arteriovenous differences of RANTES, MCP-1, and IL-6 were studied in vivo across the abdominal subcutaneous adipose tissue in healthy Caucasian subjects with a wide range of adiposity. Systemic levels and ex vivo RANTES release were studied in abdominal subcutaneous, gastric fat pad, and omental adipose tissue from morbidly obese bariatric surgery patients and in thoracic subcutaneous and epicardial adipose tissue from cardiac surgery patients without coronary artery disease. Arteriovenous studies confirmed in vivo RANTES and IL-6 release in adipose tissue of lean and obese subjects across the abdominal subcutaneous adipose tissue in obesity. However, in vivo release of MCP-1 and RANTES, but not IL-6, was lower than circulating levels. Ex vivo release of RANTES was greater from the gastric fat pad compared with omental (P < 0.01) and subcutaneous (P = 0.001) tissue. Epidiaphragmatic adipose tissue released less RANTES than thoracic subcutaneous adipose tissue in lean (P = 0.04) but not obese subjects. Indexes of obesity correlated with epicardial RANTES but not with systemic RANTES or its release from other depots. In conclusion, RANTES is released by human subcutaneous adipose tissue in vivo and in varying amounts by other depots ex vivo. While it appears unlikely that the adipose organ contributes significantly to circulating levels, local implications of this chemokine deserve further investigation.

C-C ligand 5: monocyte chemoattractant protein-1; interleukin-6; arteriovenous differences

IN OBESITY, the expanded adipose tissue is characterized by significant inflammatory infiltration and, via the secretion of multiple adipokines, contributes to chronic, low-grade inflammation and to obesity-associated pathologies such as type 2 diabetes and cardiovascular disease (1, 5, 15). Recent interest has focused on a salient member of the CC chemokine beta subfamily, regulated on activation, normal T cell expressed and secreted (RANTES), also known as C-C ligand 5 (CCL5), and its emerging role in regulating the recruitment of inflammatory cells into tissues. RANTES has been implicated in atherogenesis (2, 23), and circulating levels of the chemokine are associated with impaired glucose tolerance, type 2 diabetes (7), and other cardiovascular risk factors (9). RANTES mRNA and protein are expressed in both murine and human adipose tissue (12, 24). Murine diet-induced obesity is associated with elevated levels of RANTES and its main receptor C-C receptor 5 (CCR5) in adipose tissue, together with enhanced local T-cell accumulation (24). In human obesity this expression is elevated in omental fat (12), while data on other depots are inconclusive (22, 24). In obese subjects adipose tissue expression of RANTES and its receptors correlated positively with expression of CD68, a macrophage-specific marker. Both CD68 and RANTES were higher in both subcutaneous and omental adipose tissue of obese compared with lean patients (8).

Central obesity, with an expansion of both abdominal subcutaneous and visceral adipose tissue, is frequently associated with adverse comorbidities. Furthermore, there are stronger links between adverse outcomes and the visceral adiposity compared with subcutaneous abdominal adipose tissue deposition (6, 17). To date, studies have looked at intra-abdominal visceral depots under the assumption of homogeneity. The recently described epicardial depot is also thought to behave in a similar way to visceral depots (19). However, differences in intrinsic properties of adipose tissue, its anatomic location and pattern of venous drainage, and/or genetic/environmental influences may contribute to make these depots more heterogeneous (16).

With this in mind we hypothesized that there are depot-specific differences in the production of RANTES from human adipose tissue, and in this study we aimed to assess the relative contributions of the various depots by looking at 1) in vivo release in lean and obese subjects across the abdominal subcutaneous depot; 2) ex vivo production from two different visceral adipose tissue depots, one in close proximity to the gastrointestinal tract (gastric fat pad) and the other further away (omental), as well as abdominal subcutaneous adipose tissue from morbidly obese subjects undergoing bariatric surgery; and 3) ex vivo production from the epicardial fat, in close proximity to the myocardium, and the thoracic subcutaneous adipose tissue from lean and obese subjects, free of coronary artery disease, who underwent cardiac surgery. In addition, two previously described proinflammatory cytokines, monocyte chemoattractant protein-1 (MCP-1) and interleukin-6 (IL-6), were used as reference.
MATERIALS AND METHODS

Subjects

Study 1: arteriovenous differences of chemokines in lean and obese subjects. Healthy Caucasian volunteers were recruited by means of advertisement [age 41.0 (37.3–61.0) yr]. Lean subjects had body mass index (BMI) ≤27, and obese subjects had BMI ≥30 kg/m². Eleven lean (1 woman, 10 men) individuals [BMI 24.5 (23.0–26.3) kg/m²] and eight obese (4 women, 4 men) subjects [BMI 43.0 (34.8–45.8) kg/m²] were recruited. Arteriovenous differences of RANTES, MCP-1, and IL-6 were determined in the morning after an overnight fast.

Briefly, cannulas were inserted, under local anesthesia, into a radial artery and a superficial epigastric vein draining the abdominal subcutaneous adipose tissue (4, 14). Lines were kept patent by a slow infusion of isotonic saline. Blood samples were taken simultaneously from the two sites. Previous work has shown that venous blood from superficial epigastric veins approximates the effluent from the subcutaneous adipose tissue bed, and arteriovenous differences across abdominal adipose tissue yield results in good agreement with those of microdialysis studies (21).

Study 2(a): chemokine release from abdominal subcutaneous and visceral depots. Abdominal subcutaneous, omental, and gastric fat pad biopsies were obtained from obese [BMI 43.1 (36.9–47.6) kg/m²] Caucasian patients (n = 14, all women) undergoing laparoscopic bariatric surgery [age 44.5 (42.8–48.5) yr]. Recruitment was from the preoperative clinic.

Study 2(b): chemokine release from epicardial and thoracic subcutaneous depots. Thoracic subcutaneous and epididymal adipose tissue samples were obtained from an additional group of Caucasian patients [age 65.5 (60.5–73.8) yr] undergoing cardiac surgery because of valvular heart disease. There were eight lean (7 women, 1 man) subjects [BMI 24.7 (22.3–25.4) kg/m²] and eight obese (3 women, 5 men) individuals [BMI 31.6 (29.2–37.1) kg/m²]. These patients were also recruited from the clinic. Patients with diabetes, coronary artery disease, malignancy or terminal illness, connective tissue disease or other inflammatory conditions likely to affect cytokine levels, or severe uncontrolled hypertension, immunocompromised subjects, and subjects with substance abuse or other causes for poor compliance were excluded from both studies 2(a) and 2(b). Blood samples, after an overnight fast, were taken from an antecubital vein on the day of the operation between 7:30 and 9:30 AM, separated, and stored at −80°C until analysis.

Local Ethics Committees approved the studies, and written informed consent was obtained from all participants.

Anthropometric Measurements

BMI was calculated as the weight (kg) divided by the square of the height (m²). Blood pressure was measured with a random zero sphygmomanometer (Hawksley Gelman, Lancing, UK).

Organ Cultures

Adipose tissue samples (0.2 g of abdominal subcutaneous, omental, and gastric fat pad; 0.05 g of thoracic subcutaneous and epicardial adipose tissue) were finely minced and incubated for 24 h in serum-free medium (Cellgro, Mediatech) containing 1% (vol/vol) penicillin-streptomycin (GIBCO, Paisley, UK) at 37°C in 5% CO₂. Supernatant was harvested, snap-frozen in liquid N₂, and stored at −80°C until analysis.

Cytokine Protein Array

The assay was carried out per manufacturer’s instructions (Proteome Profiler Array, Human Cytokine Array Panel A, R & D Systems) with adipose tissue conditioned media from five patients (2 bariatric and 3 cardiac surgery). Capture antibodies to 36 cytokines/chemokines were spotted in duplicate on nitrocellulose membranes. Membranes were exposed to X-ray film (Amersham Hyperfilm ECL, GE Healthcare) for up to 3 min. Films were scanned and quantified as pixel density with Adobe Photoshop. Signals from the negative control spots (background value) were subtracted from each spot. Positive control spots were taken as 100% and other spots shown relative to this. Spots with densities <10% of the positive controls were considered negative.

Adipose Tissue Fractionation

Briefly, 0.5 g of abdominal subcutaneous and omental adipose tissue from a subset of patients was cleaned from vessels, cut into small pieces, and digested with 0.2% collagenase in a shaking water bath at 37°C and 100 rpm for 1 h. The stromal cell pellet was separated from mature adipocytes by centrifuging at 2,060 relative centrifugal force (rcf) for 15 min at 4°C. The adipocyte and stromal vascular (SV) fractions were stored at −80°C until analysis.

RNA Extraction, cDNA Synthesis, and PCR

Gastric fat pad and abdominal subcutaneous and omental adipose tissue (0.2 g) and thoracic and epicardial adipose tissue (0.1 g) were ground in liquid N₂. RNA was extracted with a commercial kit (RNeasy, Qiagen, Crawley, UK). The concentration and purity of isolated RNA were assessed by measuring the optical density at 260 nm (OD₂₆₀) and 280 nm (OD₂₈₀). cDNA was synthesized with reverse transcriptase and random oligonucleotide primers (Applied Biosystems, Roche). Specific primer sequences for Taqman RT-PCR analysis were designed with Express (Applied Biosystems, Roche). β-Actin was used as housekeeper gene. Samples were analyzed in triplicate.

Assays

Plasma glucose concentration was assayed with glucose oxidase reagent (Beckman). Serum triglycerides and total cholesterol were measured with a commercial kit (K2285, Beckman). Serum C-reactive protein was measured with a commercially available kit (Wako, Osaka, Japan).

Data are shown as medians [interquartile range (IQR)] for n subjects. Concentrations of chemokines in samples obtained simultaneously from the radial artery and the abdominal superficial epigastric vein draining the subcutaneous adipose tissue are shown. M, male; F, female; BMI, body mass index; MCP-1, monocyte chemotactic protein-1; RANTES, regulated on activation, normal T cell expressed and secreted; IL-6, interleukin-6; V-A difference, difference between concentrations measured in venous vs. arterial effluent. All comparisons between lean and obese subjects were done with Wilcoxon test for related samples.
assayed with commercial reagents (total cholesterol, Boehringer Mannheim, Lewes, UK; triglycerides, Roche Diagnostics, Welwyn Garden City, UK). HDL-cholesterol was measured by the same method after the low-density lipoproteins were quantitatively precipitated out by the addition of phosphotungstic acid in the presence of magnesium ions. LDL-cholesterol was calculated with the Friedewald formula (3). C-reactive protein (CRP) was assayed by a latex-enhanced immunoturbidimetric (agglutination) procedure, measuring the light scattered by anti-CRP antibody-latex complex. The turbidity was measured photometrically at 340 nm, which related to the concentration of the antigen (CRP). All lipid and CRP assays were performed by Dr. David Wickens, Chemical Pathology, Whittington Hospital (London, UK). RANTES, MCP-1, and IL-6 were measured with human two-site ELISAs (R & D Systems, Abingdon, UK). Human serum IL-6 concentrations were assayed with the high-sensitivity ELISA, with a limit of detection of 0.09 pg/ml. All other ELISAs for the measurements of chemokine levels in culture supernatants or serum were of normal sensitivity with inter- and intra-assay coefficients of variation <10% (R & D Systems).

Statistical Analysis

Data were analyzed with SPSS version 14 for Windows software (Statistical Package for the Social Sciences, SPSS UK, Chertsey, UK). Normality of distributions was tested with the Kolmogorov-Smirnov test. Cytokine concentrations are shown as median [interquartile range (IQR)] in text and in Tables 1 and 2. Comparison of lean and obese subjects was by Mann-Whitney U-test. Arteriovenous and between-depot differences were analyzed by Wilcoxon test. Spearman rank correlations were used for the bivariate analysis. Significance was defined as \( P \leq 0.05 \).

RESULTS

Study 1: Arteriovenous Differences of Chemokines in Lean and Obese Subjects

Chemokine concentrations are shown in Table 1. In lean subjects (\( n = 11 \)), there was significant release of RANTES (\( P = 0.04 \)) and IL-6 (\( P = 0.003 \)), but not MCP-1 (\( P = 0.33 \)), from
the abdominal subcutaneous adipose tissue (Table 1, Fig. 1). However, in obese subjects (n = 8), there was significant release of all three molecules by the subcutaneous adipose tissue: RANTES (P = 0.04), IL-6 (P = 0.01) and MCP-1 (P = 0.04) (Table 1, Fig. 1).

IL-6 levels were significantly elevated both locally and systemically in obese subjects compared with lean individuals (Table 1). Accordingly, local IL-6 secretion by the subcutaneous depot, assessed as arteriovenous difference, was enhanced in the obese subjects (P = 0.003). Obesity did not further affect RANTES and/or MCP-1 release from this depot.

Arterial and venous concentrations of RANTES showed significant interaction (r = 0.70, P = 0.007). Arteriovenous differences of RANTES correlated positively and significantly with arteriovenous differences of IL-6 (r = 0.48, P = 0.04) and MCP-1 (r = 0.47, P = 0.04).

**Study 2**

CRP, as an index of inflammation, was not different between the lean, obese, and morbidly obese patients in studies 2(a) and (b). Therefore, correlations were sought in the whole group. Serum CRP correlated significantly with BMI (r = 0.37, P = 0.05) and fasting serum insulin (r = 0.44, P = 0.04). No significant associations with serum lipids, glucose, or IL-6 were apparent. However, CRP correlated significantly with serum RANTES (r = 0.45, P = 0.02) but not with levels secreted from the different depots.

Cytokine protein array data from the patients studied (n = 5: 2 bariatric and 3 cardiac surgery) showed that of the 36 molecules specified in the array, 17 (CD40 ligand, granulocyte macrophage colony-stimulating factor (GM-CSF), IFN-γ, IL-1β, IL-2, IL-4, IL-5, IL-10, IL-12 p70, IL-17, IFN-inducible protein-10 (IP-10), I-TAC, macrophage inflammatory protein (MIP)-1α and -β, stromal cell-derived factor (SDF)-1, tumor necrosis factor (TNF)-α, soluble triggering receptor expressed in myeloid cells 1 (TERM-1)] were not released into the explant supernatant solutions in detectable levels by any of the adipose tissue depots with this technique. However, 19 were detectable [CSα, granulocyte colony-stimulating factor (G-CSF), growth-related oncogene-α (GROα), I-309, soluble ICAM-1 (sICAM-1), IL-1α, IL-1 receptor antagonist (IL-1RA), IL-6, IL-8, IL-13, IL-16, IL-17E, IL-23, IL-27, IL-32a, MCP-1, macrophage migration inhibitory factor (MIF), type 1 plasminogen activator inhibitor (PAI-1), RANTES], and from those GROα, IL-6, IL-8, MIF, and PAI-1 were above 50% of the positive control in all the samples. RANTES expression varied between the different depots studied, with release from the gastric fat pad being highest (Fig. 2).

**Study 2(a): chemokine release from abdominal subcutaneous and visceral depots.** In the morbidly obese group, plasma chemokine levels did not correlate with indexes of obesity, glucose, insulin sensitivity, or blood pressure. However, serum RANTES inversely correlated with HDL-cholesterol (r = -0.62, P = 0.02), serum IL-6 (r = -0.68, P = 0.008), and serum leptin levels (r = -0.67, P = 0.01).

RANTES was released in significantly higher amounts, per gram of tissue, from the gastric fat pad compared with the omental (P = 0.01) or subcutaneous (P = 0.001) depots (n = 14; Fig. 3). This was in agreement with data from the protein array (Fig. 2). However, neither MCP-1 nor IL-6 release was significantly different between the depots in this population.

**INTERACTIONS BETWEEN CHEMOKINES FROM VARIOUS DEPOTS.** Subcutaneous RANTES release correlated significantly with that from omental tissue (r = 0.54, P = 0.05). Also, the release of RANTES from both of these depots correlated significantly with omental MCP-1 (for subcutaneous RANTES r = 0.66, P = 0.02; for omental RANTES r = 0.80, P = 0.001) and omental IL-6 (for subcutaneous RANTES r = 0.62, P = 0.02; for omental RANTES r = 0.55, P = 0.04). There were no significant correlations between the release of other chemokines from the different depots.

release from various human adipose tissue depots rather than its expression, with some insight into its potential to act as a paracrine or endocrine factor.

Adipose tissue is known to express a constantly increasing number of chemokines and cytokines, and our protein array data confirm these findings. However, not all of these are actively secreted into the circulation (14). We show that systemic levels of RANTES are ~100-fold higher than those being released from any of the adipose tissue depots studied. Therefore, it would be reasonable to suggest that while adipose tissue is able to produce this chemokine, its contribution to systemic levels may be less significant. This was further confirmed by a lack of association between its circulating levels and indexes of obesity. In contrast, IL-6 production from the subcutaneous (14) as well as the visceral (5) depots contributes significantly to the systemic circulation, with the potential to have endocrine effects on various organs, especially in obesity.

Wu et al. (24) found higher RANTES mRNA levels in visceral compared with subcutaneous adipose tissue in obese humans. In our study we assessed two distinct intra-abdominal depots, as well as subcutaneous adipose tissue, simultaneously from the same morbidly obese patients undergoing bariatric surgery. The gastric fat pad is in close proximity to the stomach, in the angle of His. It is not described in the literature in detail, and we are not aware of studies comparing it to the omental depot. This depot is highly vascularized and may become thickened in morbidly obese subjects, while its resection may prevent obstruction after gastric banding (18, 20). The gastric fat pad releases significantly more RANTES than either the omental or subcutaneous depots, perhaps because of local regulation by gastrointestinal factors. The close association between omental and subcutaneous RANTES, but not gastric fat pad RANTES, may also imply that this depot is independently regulated.

The epicardial adipose tissue is in close proximity to the myocardium and the coronary arterial tree (10). Its increased ability for fatty acid incorporation and lipogenesis on one hand, and for fatty acid release on the other, implies that it primarily serves as a local energy source to the adjacent myocardium and/or as a scavenger of circulating free fatty acids, which are known to be toxic for cardiomyocytes and can also affect electrical conductivity in the heart (10, 11). Previously, in a population with coronary artery disease, increased expression of IL-1β, TNF-α, IL-6, IL-6 soluble receptor, and MCP-1 was described in epicardial compared with subcutaneous adipose tissue (13). Here, we report ex vivo release of RANTES from the epicardial adipose tissue in individuals free of coronary artery disease. Epicardial, but not subcutaneous, RANTES release correlates positively with BMI and is enhanced in obese individuals.

In summary, we show release of RANTES from both subcutaneous adipose tissue in vivo and release of this chemokine from novel depots, the gastric fat pad and epicardial fat. While epicardial RANTES is related to obesity, neither systemic RANTES nor its release from the subcutaneous and the abdominal visceral adipose tissue is a good marker of adiposity. There is significant heterogeneity in the release of RANTES from the various depots, a finding that suggests differential regulation by autocrine/paracrine factors. A weakness of this study is that the abdominal and thoracic depots are from different subjects, and therefore direct comparisons are difficult. Elevated RANTES expression in the adipose tissue of diet-induced obese male mice is associated with increased T-cell infiltration, suggesting paracrine chemotactic effects (24). Given that in other cell populations RANTES affects intracellular pathways that are central to adipocyte biology (25, 26), it would be interesting in the future to evaluate adipose tissue as a target, rather than as a source, of RANTES.
