Kao C, Hsu J, Bandi V, Jahoor F. Alterations in glutamine metabolism and its conversion to citrulline in sepsis. Am J Physiol Endocrinol Metab 304: E1359–E1364, 2013. First published April 23, 2013; doi:10.1152/ajpendo.00628.2012.—In enterocytes, glutamine serves as the major source of energy; another metabolic fate of glutamine is conversion to citrulline. Because sepsis can affect gut function and integrity, alterations in glutamine metabolism may exist and lead to decreased citrulline production. This study aimed to investigate how sepsis affects glutamine metabolism, including its conversion to citrulline, by measuring glutamine and citrulline flux, fractional splanchnic extraction of glutamine and leucine, and the contribution of glutamine nitrogen to citrulline in septic patients and healthy controls. Eight patients with severe sepsis and 10 healthy controls were given primed, constant intravenous infusion of \(^{2}\text{H}_2\text{citrulline}\) and sequential administration of intravenous and enteral \([\alpha^{-15}\text{N}]\text{glutamine}\) and \([^{13}\text{C}]\text{leucine}\) in the postabsorptive state. The results showed that, compared with healthy controls, septic patients had a significantly lower whole body citrulline flux and plasma concentration, higher endogenous leucine flux, and higher glutamine clearance. Fractional splanchnic extraction of leucine was higher in septic patients than in controls, but fractional extraction of glutamine was not different. The majority of the \(^{15}\text{N}\) label transferred from glutamine to citrulline was found at the \(\alpha\)-position. These results demonstrate that lower glutamine plasma concentrations in sepsis were a result of increased glutamine clearance. Despite adequate splanchnic uptake of glutamine, there is decreased production of citrulline, suggesting a defect in the metabolic conversion of glutamine to citrulline, decreased uptake of glutamine by the enterocyte but increased uptake by the liver, and/or shunting of glutamine to other metabolic pathways.

severe sepsis; stable isotopes; enterocyte

THE GUT IS BELIEVED TO PLAY an important role in sepsis. In fact, it has been postulated that the gut can initiate, perpetuate, or exacerbate the systemic inflammatory response syndrome (SIRS) and lead to the development of multiorgan dysfunction syndrome (MODS) (29). Sepsis can affect gut function and mucosal integrity via a variety of mechanisms, including ischemia-reperfusion injury, mitochondrial dysfunction, and increased intestinal permeability (9). Because maintenance of gut mucosal integrity depends almost exclusively on an adequate enteral supply of amino acids both as primary source of fuel and as substrate for protein synthesis, more information is needed about the metabolic fates of enterally administered amino acids in sepsis.

In health, the gastrointestinal tract is the major organ of glutamine utilization (32). Glutamine is the major source of energy for proliferating enterocytes, providing energy for ATP-dependent processes, including rapid intracellular protein turnover and nutrient transport (39). Adult rat enterocytes extract 25–33% of arterial glutamine and 66% of luminal glutamine (39). Normally the most abundant amino acid in human plasma and muscle (3), glutamine becomes conditionally essential during sepsis, because the need for glutamine exceeds its endogenous rate of synthesis (18). Low plasma glutamine concentrations are found in patients with sepsis (16), and in critically ill patients, low glutamine concentrations are correlated with mortality (4, 28). At present there is a paucity of data on the mechanism(s) responsible for this reduction of glutamine in sepsis.

Along with its use by the gut for energy production and protein synthesis, another metabolic fate of glutamine in the gut is its conversion to citrulline in enterocytes (6). In addition, citrulline is a modulator of protein anabolism (7) and is the only precursor for de novo synthesis of arginine in the body. Low plasma citrulline concentrations in sepsis are the result of decreased citrulline production (16, 22). This decrease in citrulline synthesis may be caused by reduced availability of glutamine or impaired metabolic conversion of glutamine to citrulline within the enterocyte. At present, there are no data on the mechanism responsible for this reduction of citrulline in sepsis.

Recently, there has been some controversy about the exact role of glutamine as a precursor for citrulline synthesis. Windmueller and Spaeth first demonstrated the importance of glutamine as a precursor for citrulline synthesis (37), and subsequent stable isotope tracer studies using an \([\alpha^{-15}\text{N}]\) glutamine tracer reported that \(~80\%\) of citrulline is derived from glutamine in fasted humans (20, 35). However, the role of glutamine as a carbon skeleton donor to citrulline has recently been questioned. Marini et al. (16) examined the relationship between glutamine and citrulline in fed mice by use of different isotopomer tracers of glutamine. They reported that glutamine is a poor carbon skeleton donor for the synthesis of citrulline but rather contributes nonspecific nitrogen and carbon to citrulline synthesis (24). On the other hand, in a study of fed humans, Tomlinson et al. (17) found significant synthesis of arginine from the carbon skeleton of dietary glutamine, as well as transfer of the amino N of glutamine to arginine largely via transamination, providing indirect evidence that glutamine contributes both carbon and nitrogen to citrulline synthesis.

The primary aim of this study was to investigate how glutamine metabolism is affected by sepsis; the secondary aim was to characterize the metabolic conversion of glutamine to citrulline. Using stable isotope tracers, we measured the rate of glutamine entry into the plasma, whole body citrulline flux, glutamine clearance, splanchnic extraction of glutamine, and the fraction of administered glutamine used for citrulline synthesis in patients with sepsis and healthy controls. Splanchnic...
metabolism of glutamine was compared with splanchnic metabolism of leucine, an essential amino acid. We hypothesized that the lower plasma glutamine seen in patients with sepsis is due to decreased rate of entry into the plasma plus increased utilization (clearance), that glutamine is the main carbon precursor for the synthesis of citrulline, and that the rate of de novo citrulline production is directly related to the rate of splanchnic extraction of dietary glutamine.

**MATERIALS AND METHODS**

**Study subjects.** The study was reviewed and approved by the Institutional Review Board of Baylor College of Medicine in Houston, Texas. Eight adult patients admitted with severe sepsis to the Medical Intensive Care Unit (MICU) at Ben Taub General Hospital in Houston were enrolled in the study. Severe sepsis was defined according to the International Sepsis Definition Conference (19), and all patients were receiving mechanical ventilation. Septic patients were studied within 48 h of admission to the MICU. None of the patients were receiving chronic systemic corticosteroids equivalent to 10 mg/day prednisone or higher or had a diagnosis of end-stage renal disease or solid organ malignancy.

Ten healthy adult volunteers participated in the study as control subjects. All control subjects were in good health as established by medical history, physical examination, and blood chemistry measurements. They were selected to be similar in age, sex, and body mass index (BMI) to the patients. All patients and controls were enrolled after written, informed consent was obtained.

**Isotope tracer infusion.** Tracer infusions were performed in healthy subjects at either the adult General Clinical Research Center (GCRC) of Baylor College of Medicine or the Metabolic Research Unit (MRU) of the Children’s Nutrition Research Center. Tracer infusions were performed in the septic patients in the MICU at Ben Taub General Hospital. Sterile solutions of [1-13C]leucine, [α-15N]glutamine, and [5,5-2H2]citrulline (99%; Cambridge Isotope Laboratories, Woburn, MA) were prepared in normal saline using strict aseptic techniques (1,5). After a baseline blood sample was obtained, a primed, continuous infusion of the isotope (20) was started and maintained for 7 h. The use of heated dorsal hand vein sampling as a surrogate of intracellular leucine, was measured by negative chemical ionization gas chromatography-mass spectrometry (GC-MS) at the Children’s Nutrition Research Center. Tracer infusions were calculated as the product of the fraction of tracer extracted by 100.

**Calculations.** The rate of appearance or total flux (Q) of leucine, glutamine, and citrulline were calculated from the steady-state equation

$$Q \left(\text{mol} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}\right) = \left(\frac{E_{\text{inf}}}{E_{\text{pl}}}\right) \times i$$

where $E_{\text{inf}}$ is the isotopic enrichment of leucine, glutamine, or citrulline in the plasma of the enteral and intravenous tracers (leucine and glutamine), and $i$ is the infusion rate of the tracer ($\text{mol} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$). Endogenous leucine and citrulline fluxes were determined by subtracting their infusion rates, $i$, from $Q$.

Under steady-state conditions, the rate of appearance of glutamine equals the rate of disappearance. Therefore, glutamine clearance ($\text{ml} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) was calculated as

$$Q_{\text{Gl}} = \text{plasma glutamine concentration}$$

The percentage of the enteral tracer of leucine or glutamine extracted by the splanchnic tissues was calculated from

$$\% \text{AA}_{\text{plan}} = \left[1 - \left(\frac{E_{\text{EN}}}{E_{\text{IV}}}ight) \times \left(\frac{i_{\text{IV}}}{i_{\text{EN}}}ight)\right] \times 100$$

where $E_{\text{EN}}$ and $E_{\text{IV}}$ are the plateau isotopic enrichments in the plasma of the enteral and intravenous tracers (leucine and glutamine), and $i_{\text{IV}}$ and $i_{\text{EN}}$ are the infusion rates of the intravenous and enteral tracers. Absolute splanchnic extraction of the leucine or glutamine tracer was calculated as the product of the fraction of tracer extracted by the splanchnic tissues and the enteral tracer infusion rate.

The fraction of administered glutamine tracer used for citrulline production was calculated from

$$F_{\text{GLN} \rightarrow \text{CIT}} = \left(\frac{E_{\text{CTT}_{\text{GLN}}}}{E_{\text{CTT}} \times i_{\text{IV}} \times i}\right) \times 100$$

where $E_{\text{CTT}_{\text{GLN}}}$ is the plateau isotopic enrichment in plasma of [α-15N]glutamine, $Q_{\text{CTT}}$ is the citrulline flux, $E_{\text{inf}}$ is the isotopic enrichment of the glutamine tracer, and $i$ is the infusion rate of glutamine.

Statistics. Continuous variables were summarized by group as means ± SE unless otherwise indicated. Differences between groups of subjects were assessed by the unpaired Student’s t-test. Differences in the isotopomer distribution of categorical variables were compared using χ² test. Tests were considered statistically significant if P < 0.05. Correlations were performed using Pearson’s correlation. Data analysis was performed with STATA software (version 11).

RESULTS

Subject characteristics. The characteristics of the patients and controls are presented in Table 1. There were no significant differences in age, sex, or BMI between the two groups. Of the patients with sepsis, all had respiratory failure and were intubated and required mechanical ventilation, and five of the eight patients had septic shock. The source of sepsis was pneumonia in five patients, meningitis in one patient, endocarditis in one patient, and septic emboli in one patient. Blood cultures were positive in 50% of the patients (pneumococcus in 2, methicillin-resistant staphylococcus aureus in 1, and citrobacter freundi in 1). Patients had an APACHE II score of 23.0 ± 2.0 (mean ± SE), and three died during their hospitalization. Septic patients had significantly higher plasma concentrations of C-reactive protein than controls.

Leucine, glutamine, and citrulline kinetics and plasma concentrations. The amino acid kinetics and plasma concentrations are presented in Tables 2 and 3. Because leucine is an essential amino acid, in the fasted state its flux is derived only from whole body protein breakdown. Therefore, the endogenous flux of leucine is an index of the rate of whole body protein breakdown. Endogenous leucine flux was significantly higher in patients with sepsis than in controls (P = 0.01; Table 2). Glutamine flux reflects the interorgan transport rates of glutamine through plasma (8). There was no difference in glutamine flux between patients and controls (P = 0.51), but the plasma concentration of glutamine was significantly lower in the patients (P < 0.001; Table 3) due to an increase in its clearance from the plasma (P = 0.003). Septic patients had a significantly lower citrulline flux (P < 0.001) as well as plasma citrulline concentration (P < 0.001) compared with controls.

There was a significant correlation between plasma glutamine and citrulline concentrations (r = 0.77, P < 0.001). There were also significant correlations between citrulline flux and citrulline plasma concentration (r = 0.84, P < 0.001) and citrulline flux and plasma glutamine concentration (r = 0.78, P < 0.001). There was a significant correlation between glutamine flux and endogenous leucine flux when one outlying value was removed (r = 0.68, P = 0.003).

Splanchnic extraction of leucine and glutamine. Percent splanchnic extraction of the leucine tracer was significantly higher in septic patients than in controls (P = 0.045), and there was a trend toward a higher absolute extraction of the tracer in sepsis (P = 0.051). There was no difference in percent splanchnic extraction or absolute splanchnic extraction of the glutamine tracer in the two groups (P = 0.17). These results are summarized in Table 4. The ratio of [13C]KICA to [13C]leucine in the plasma was 0.63 ± 0.05 in septic patients and 0.71 ± 0.03 in controls when the tracer was given intravenously, and 0.84 ± 0.06 in septic patients and 0.77 ± 0.07 in controls when the tracer was given enterally. This ratio was significantly higher when given enterally compared with intravenously in the septic patients (P = 0.01).

As shown in Fig. 1, the fraction of administered glutamine used for citrulline production when it was given enterally was lower in septic patients than in controls (P = 0.01). A greater amount of glutamine was used for citrulline synthesis when it was given intravenously, and 0.84 ± 0.06 in septic patients and 0.77 ± 0.07 in controls when the tracer was given enterally. This ratio was significantly higher when given enterally compared with intravenously in the septic patients (P = 0.01). The majority of the [15N]arginine tracer was extracted by the splanchnic bed (93.5 ± 0.7%), more than any other organ or tissue.

AJP-Endocrinol Metab • doi:10.1152/ajpendo.00628.2012 • www.ajpendo.org
Sepsis.

In a study of healthy volunteers given endotoxin, net splanchnic uptake of leucine compared with controls but did not have a significant change in glutamine splanchnic uptake. Septic patients in this study had a 67% greater splanchnic uptake of leucine similarly increased 76%, from 21 ± 3% to 37 ± 7% (10). The ultimate fate of leucine taken up by the splanchnic bed in this study cannot be determined, as leucine oxidation was not measured. However, Matthews et al. (26) showed that the majority was either converted to KICA or taken up for incorporation to newly synthesized protein. We found that, in both septic patients and controls, the ratio of KICA to leucine isotopic enrichments was increased when leucine was administered enterally compared with intravenously, although this difference is greater in the septic patients. This suggests that enteral leucine is undergoing transamination to KICA.

During health the small intestine is the principal organ of glutamine uptake, but in sepsis the liver is the major site of glutamine consumption, and there is a decrease in intestinal glutamine uptake (2, 31). The tracer methodologies used in this study cannot distinguish between retention of amino acids by the gut and first-pass clearance of amino acids by the liver. However, because it is likely that glutamine uptake by the liver is increased, this suggests that uptake of glutamine by the gut may be decreased. The different responses in splanchnic metabolism of leucine and glutamine in sepsis may be due to changes in utilization of these amino acids rather than a consequence of gut dysfunction. Of note, these studies were

\[ \text{Glu} \rightarrow \text{KICA} \rightarrow \text{Leucine} \]

Our finding of splanchnic extraction of glutamine and leucine. The present study aimed to investigate how sepsis affects glutamine metabolism, with emphasis on its conversion to citrulline, in patients with severe sepsis or septic shock and in healthy controls. To our knowledge, this is the first study to examine the relationship between splanchnic glutamine extraction and citrulline production as well as the contribution of glutamine nitrogen to citrulline in septic humans. Contrary to our hypothesis, the fractional splanchnic extraction of glutamine was not different in sepsis vs. controls, although the fraction of administered glutamine used for citrulline production was lower in sepsis, suggesting that factors other than diminished supply of glutamine lead to decreased citrulline production. In support of this, we also found that in sepsis there is a greater proportion of nitrogen label transferred from \([\alpha,15N]\)glutamine to citrulline at the \(\alpha\)- and ureido positions relative to the \(\delta\)-position, indicating a possible defect in the nitrogen transfer via transamination to glutamate semialdehyde by the enzyme ornithine transaminase.

**DISCUSSION**

Splanchnic extraction of glutamine and leucine. Our finding that in healthy controls the fractional extraction of glutamine was \(39.9 \pm 4.5\%\), and the fractional splanchnic extraction of leucine was \(18.0 \pm 3.2\%\) is consistent with prior studies in healthy humans showing that \(~40–75\%\) of enterally administered glutamine (13, 25, 33) and \(18–23\%\) of enterally administered leucine (14, 26) undergo first-pass extraction within the splanchnic bed. Septic patients in this study had a 67\% greater splanchnic uptake of leucine compared with controls but did not have a significant change in glutamine splanchnic uptake. In a study of healthy volunteers given endotoxin, net splanchnic uptake of leucine similarly increased 76\%, from \(21 \pm 3\%\) to \(37 \pm 7\%\) (10). The ultimate fate of leucine taken up by the splanchnic bed in this study cannot be determined, as leucine oxidation was not measured. However, Matthews et al. (26) showed that the majority was either converted to KICA or taken up for incorporation to newly synthesized protein. We found that, in both septic patients and controls, the ratio of KICA to leucine isotopic enrichments was increased when leucine was administered enterally compared with intravenously, although this difference is greater in the septic patients. This suggests that enteral leucine is undergoing transamination to KICA.

During health the small intestine is the principal organ of glutamine uptake, but in sepsis the liver is the major site of glutamine consumption, and there is a decrease in intestinal glutamine uptake (2, 31). The tracer methodologies used in this study cannot distinguish between retention of amino acids by the gut and first-pass clearance of amino acids by the liver. However, because it is likely that glutamine uptake by the liver is increased, this suggests that uptake of glutamine by the gut may be decreased. The different responses in splanchnic metabolism of leucine and glutamine in sepsis may be due to changes in utilization of these amino acids rather than a consequence of gut dysfunction. Of note, these studies were
performed in the postabsorptive state, and intestinal response to a tracer in the fed state may be different.

Glutamine metabolism. Endogenous leucine flux, an index of whole body protein breakdown, was greater in patients with sepsis than in controls, a finding that is consistent with studies in both animals and humans (17, 38, 40). Because glutamine is present in high concentrations in all organs and tissues, glutamine can account for as much as 50% of amino acids released from whole body protein breakdown (38). Accordingly, we found a significant correlation between endogenous leucine flux and glutamine rate of entry into the plasma, indicating that glutamine entry into the plasma is closely related to its release from protein breakdown. However, despite the faster rate of protein breakdown in the septic patients, glutamine entry into plasma was not also increased. This finding is consistent with a previous study of glutamine and leucine kinetics in critical illness (15). The plasma concentration of glutamine in septic patients was significantly lower compared with controls despite a similar rate of entry into the plasma compartment, confirming that rate of glutamine removal exceeded its rate of entry into the plasma. This was supported by the increased rate of clearance of glutamine by the septic patients.

Glutamine as a precursor of citrulline. Our data suggest indirectly that glutamine serves as a carbon precursor for citrulline. In both septic patients and healthy controls, the majority of the $^{15}$N label (more than 70%) from glutamine was found on the $\alpha$-nitrogen of citrulline. This is in contrast to the results of Marini et al. (24), who found that after infusion of $[\alpha-^{15}\text{N}]$glutamine, $[1^{15}\text{N}]$citrulline had the greatest enrichment at the ureido position. On the other hand, Tomlinson et al. (34) found the highest $^{15}\text{N}$ enrichment at the $\delta$-position of citrulline after administration of $[\alpha-^{15}\text{N}]$glutamine. Differences in study design and isotopomer analysis may explain these differences, as the first study was performed in mice, and although the other study was in humans, it was in the fed state. Although the carbon skeleton of glutamine was not labeled in our study, the $\alpha$-nitrogen of glutamine is transferred along with the carbon skeleton in the pathway to form $[\alpha-^{15}\text{N}]$citrulline, indicating that glutamine also serves as a carbon donor for glutamine. Additionally, no labeled ornithine was administered; thus, ornithine could be a major contributor of carbon to citrulline. Finally, healthy controls, but not septic patients, had significant labeling at the $\delta$-N position of citrulline. This suggests a defect in the transfer of nitrogen by transamination via ornithine aminotransferase. Together, the findings that less administered $[\alpha-^{15}\text{N}]$glutamine is used to form $[\alpha-^{15}\text{N}]$citrulline in sepsis combined with a decrease in nitrogen transfer to citrulline at the $\delta$-position suggests defect(s) in the metabolic pathway between glutamine and citrulline, not just an inadequate supply of precursor.

Glutamine supplementation in critical illness. Because of the finding of low plasma glutamine in sepsis, exogenous glutamine supplementation has been studied in large clinical trials. However, the metabolic effects of exogenous glutamine supplementation remain poorly understood. Current guidelines recommend intravenous glutamine supplementation in parenterally fed critically ill patients (30) on the basis of evidence that parental, but not enteral, glutamine supplementation may affect mortality and infectious complications (11, 12, 27). It has been hypothesized that the benefit of exogenous glutamine may be from its conversion to citrulline and then to arginine (36). However, the metabolic data here do not support this hypothesis for multiple reasons. First, we found that a very small percentage of glutamine is used for the synthesis of citrulline, a finding consistent with a prior study of humans during surgery (21). Second, we found that about twice as much glutamine tracer was used for citrulline synthesis when it was administered enterally compared with intravenously. Thus, if its mechanism of action were through citrulline, glutamine’s clinical benefit should be greater when given enterally. In fact, because enteral administration of amino acids leads to uptake and utilization in the intestines, there is less delivery to the peripheral tissues with dietary supplementation. Therefore, the benefit of parenteral over enteral glutamine during critical illness suggests that its effect on peripheral tissues is of greater importance. On the other hand, if one potential benefit of glutamine supplementation is to improve gut barrier function, its effect may be greater if administered enterally and prior to the onset of MODS, even in fasting patients.

Study limitations. This study had several limitations. Sepsis is a heterogeneous syndrome; therefore, the findings in this small sample may not be generalizable to all patients with sepsis. The subjects selected for the study had severe sepsis or septic shock with a mean APACHE II score of 23 ± 2. Nevertheless, significant differences were seen in splanchic leucine extraction, citrulline flux, and the conversion of glutamine to citrulline. Also, the methods used in this study could not distinguish between intestinal and liver uptake during first-pass metabolism of tracers. However, this could not be done without invasive procedures and sampling of the portal circulation. Finally, the study was conducted only in the fasted state, and utilization and metabolism of glutamine may change in the fed state.

Conclusions. Despite adequate splanchnic uptake of glutamine, there is decreased production of citrulline, suggesting there is 1) a defect in one or more steps in the metabolic conversion of glutamine to citrulline, 2) decreased uptake of glutamine by the enterocyte but increased uptake by the liver, and/or 3) shunting of glutamine to other metabolic pathways. The findings of this study suggest that the beneficial effect of glutamine supplementation is probably not via enhanced citrulline and arginine production but rather from the delivery of glutamine to the peripheral tissues.
